I. INTRODUCTION

A. Path integral solution of diffusion processes

There are three equivalent mathematical representations of a diffusion process, provided of course that boundary and initial conditions can be properly specified in each representation. In this paper we refer to all three representations.

The Langevin rate equation for a stochastic process in dS can be written as in a prepoint discretization

$$\begin{aligned} dS &= f dt + g dW, \\ \langle dW \rangle &= 0, \\ \langle dW(t)dW(t') \rangle &= dt \delta(t-t'), \end{aligned} \quad (1)$$

for general drift f and standard deviation g that may depend on S and t , wherein f and g are understood to be evaluated at the prepoint t . Here, we just consider S dependent cases, but our algorithm can easily be extended to time dependent cases and to multivariate systems.

This corresponds to a Fokker-Planck equation representing the short-time conditional probability P of evolving within time dt ,

$$\frac{\partial P}{\partial t} = -\frac{\partial(fP)}{\partial S} + \frac{1}{2} \frac{\partial^2(g^2P)}{\partial S^2}, \quad (2)$$

where the diffusion is given by g^2 .

The path-integral representation for P for the short-time propagator is given by

$$\begin{aligned} P(S', t' | S, t) &= \frac{1}{2\pi g^2 \Delta t} \exp(-L dt), \\ L &= \frac{\left(\frac{dS}{dt} - f\right)^2}{2g^2}, \end{aligned}$$

$$\frac{dS}{dt} = \frac{S' - S}{dt}, \quad dt = t' - t. \quad (3)$$

In the above we have explicitly used the prepoint discretization [1].

B. PATHINT motivation from previous study

In the above we have explicitly used the prepoint discretization, wherein f and g are understood to be evaluated at the prepoint t . In this paper, we do not require multivariate generalizations, or issues dealing with other discretizations, or explication of long-time path-integral evaluations, or issues dealing with Riemannian invariance of our distributions. There exist other references dealing with these issues in the context of calculations presented here [2–5].

Our approach is motivated by a multivariable generalization of a numerical path-integral algorithm [6–8], PATHINT, used to develop the long-time evolution of the short-time probability distribution as used in several studies in chaotic systems [9,10], neuroscience [11,9,12], and financial markets [3]. These studies suggested that we apply some aspects of this algorithm to the standard binomial tree.

C. PATHTREE algorithms

Tree algorithms are generally derived from binomial random walks [13]. For many applications, “tree” algorithms are often used, corresponding to the above Langevin and Fokker-Planck equations [14,15]. These algorithms have typically been only well defined for specific functional forms of f and g .

We have previously presented a powerful PATHINT algorithm to deal with quite general f and g functions [3]. This general PATHTREE algorithm can be used beyond previous specific systems, affording fast reasonable resolution calculations for probability distributions of a large class of nonlinear diffusion problems.

D. Organization of paper

Section II describes the standard tree algorithm. Section III develops our probability PATHTREE algorithm. Section IV presents our probability calculations. Section V is our conclusion.

II. STANDARD OPTION TREE ALGORITHM

A. Binomial tree

In a two-step binomial tree, the step up Su or step down Sd from a given node at S is chosen to match the standard deviation of the differential process. The constraints on u and d are chosen as

$$ud=1. \quad (4)$$

If we assign probability p to the up step Su , and $q=(1-p)$ to the down step Sd , the matched mean and variance are

$$pSu+(1-p)Sd=\langle S(t+\Delta t)\rangle,$$

$$S^2[pu^2+qd^2-(pu+qd)^2]=\langle [S(t+\Delta t)-\langle S(t+\Delta t)\rangle]^2\rangle. \quad (5)$$

The right-hand side can be derived from the stochastic model used.

B. Trinomial tree

The trinomial tree can be used as a robust alternate to the binomial tree. Assume p_u , p_m , and p_d are the probabilities of up jump Su , middle (no-)jump S , and down jump Sd , where the jumps are chosen to match the standard deviation. To match the variance of the process, the equations must satisfy

$$p_u+p_m+p_d=1,$$

$$S(p_uu+p_m+p_dd)=\langle S(t+\Delta t)\rangle,$$

$$S^2[p_uu^2+p_m+p_dd^2-(p_uu+p_m+p_dd)^2]=\langle [S(t+\Delta t)-\langle S(t+\Delta t)\rangle]^2\rangle. \quad (6)$$

III. PROBABILITY TREE ALGORITHM

A. General diffusion process

Consider the general Markov multiplicative diffusion process interpreted as an Itô prepoint discretized process, Eq. (1) with drift f and diffusion g^2 . For financial option studies the particular form of the drift bS and diffusion $(\sigma S)^2$ is chosen for lognormal Black-Scholes (BS) calculations [14]. For options, the coefficient b is the cost of carry, e.g., $b=r$, the risk-free rate, when S is a stock price, and $b=0$ when S is a future price [16]. The case of drift bS and constant diffusion σ^2 corresponds to the Ornstein-Uhlenbeck (OU) process [17].

Our formalism is general and can be applied to other functional forms of interest with quite general nonlinear drifts and diffusions, of course provided that the region of solution does not violate any boundary or initial conditions.

Statistical properties of the dS process and of any derivative based on nonlinear transformations applied to S are determined once the transition probability distribution function $P(S,t|S_0,t_0)$ is known, where the 0 index denotes initial values of time and of the stochastic variable S . Transforma-

tion are common and convenient for BS,

$$z=\ln S, \quad (7)$$

yielding a simple Gaussian distribution in z , greatly simplifying analytic and numerical calculations.

The probability distribution can be obtained by solving the associated forward Fokker-Planck equation (2). Appropriate boundaries and initial condition must be specified, e.g., $P(S|S_0)=\delta(S-S_0)$.

In general cases, the Fokker-Planck equation is rather difficult to solve, although a vast body of work is devoted to it [17]. The particular BS and OU cases possess exact results.

Our goal is to obtain the solution of Eq. (1) for the more general process. A quite general code, PATHINT [3], works fine, but it is much slower than the PATHTREE algorithm we present here.

B. Deficiency of standard algorithm to order $\sqrt{\Delta t}$

We briefly describe the Cox-Ross-Rubenstein construction of the binomial tree approximation [18].

A tree is constructed that represents the time evolution of the stochastic variable S . S is assumed to take only two values, u (up value), and d (down value) at moment t , given the value S at moment $t-\Delta t$. The probabilities for the up and down movements are p and q , respectively. The four unknowns $\{u,d,p,q\}$ are calculated by imposing the normalization of the probability and matching the first two moments conditioned by the value S at $t-\Delta t$, using the variance of the exact probability distribution $P(S,t|S_0,t_0)$. One additional condition is arbitrary and is usually used to symmetrize the tree, e.g., $ud=1$.

The main problem is that the above procedure cannot be applied to a general nonlinear diffusion process as considered in Eq. (1), as the algorithm involves a previous knowledge of terms of $O(\Delta t)$ in the formulas of quantities $\{u,p\}$ obtained from a finite time expansion of the exact solution P sought. Otherwise, the discrete numerical approximation obtained does not converge to the proper solution.

This observation can be checked analytically in the BS CRR case by replacing the relation $u=\exp(\sigma\Delta t)$ [15] with $u=1+\sigma\sqrt{\Delta t}$, and deriving the continuous limit of the tree. This also can be checked numerically, as when $\{u,p\}$ are expanded to $O(\Delta t)$, the proper solution is obtained.

C. Probability PATHTREE algorithm

As mentioned previously, a general path-integral solution of the Fokker-Planck equation, including the Black-Scholes equation, can be numerically calculated using the PATHINT algorithm. Although this approach leads to very accurate results, it is computationally intensive.

In order to obtain tree variables valid up to $O(\Delta t)$, we turn to the short-time path-integral representation of the solution of the Fokker-Planck equation, which is just the multiplicative Gaussian-Markovian distribution [19,1]. In the prepoint discretization relevant to the construction of a tree

$$P(S', t' | S, t) = \frac{1}{\sqrt{2\pi\Delta t}g^2} \exp\left(-\frac{(S' - S - fdt)^2}{2g^2\Delta t}\right),$$

$$\Delta t = t' - t, \quad (8)$$

valid for displacements S' from S “reasonable” as measured by the standard deviation $g\sqrt{\Delta t}$, which is the basis for the construction of meshes in the PATHINT algorithm.

The crucial aspects of this approach are: There is no *a priori* need of the first moments of the exact long-time probability distribution P , as the necessary statistical information to the correct order in time is contained in the short-time propagator. The mesh in S at every time step need not recombine in the sense that the prepoint-postpoint relationship be the same among neighboring S nodes, as the short-time probability density gives the correct result up to order $O(\Delta t)$ for any final point S' . Instead, we use the natural metric of the space to first lay down our mesh, then dynamically calculate the evolving local short-time distributions on this mesh.

We construct an additive PATHTREE algorithm, starting with the initial value S_0 , with successive increments

$$S_{i+1} = S_i + g\sqrt{\Delta t}, S_i > S_0,$$

$$S_{i-1} = S_i - g\sqrt{\Delta t}, S_i < S_0, \quad (9)$$

where g is evaluated at S_i . We define the up and down probabilities p and q , respectively, in an abbreviated notation, as

$$p = \frac{P(i+1|i;\Delta t)}{P(i+1|i;\Delta t) + P(i-1|i;\Delta t)},$$

$$q = 1 - p, \quad (10)$$

where the short-time transition probability densities P 's are calculated from Eq. (8). Note that in the limit of small Δt ,

$$\lim_{\Delta t \rightarrow 0} p = \frac{1}{2}. \quad (11)$$

1. Continuous limit of the PATHTREE algorithm

In either the upper or lower branches of the tree ($S_i > S_0$ or $S_i < S_0$, respectively), we always have the postpoint $S_{i\pm 1}$ in terms of the prepoint S_i , but we also need the inverses to find the asymptotic $\lim_{\Delta t \rightarrow 0}$ of our PATHTREE building technique. For example, for the upper branch case

$$S_{i-1} \approx S_i - g\sqrt{\Delta t} + \left(g \frac{\partial g}{\partial S}\right) \Delta t + O(\Delta t^{3/2}). \quad (12)$$

This expression must be used to extract the down change d ($S_{i-1} = S_i + d$), for comparison to the standard tree algorithm.

The continuous limit of the previous tree building procedure is obtained by Taylor expanding all factors up to terms $O(\Delta t)$ and as functions of the prepoint S_i [15]. This leads to

$$\frac{pu + qd}{\Delta t} \approx f + O(\Delta t^{1/2}),$$

$$\frac{pu^2 + qd^2}{\Delta t} \approx g^2 + O(\Delta t^{1/2}), \quad (13)$$

from which the correct partial differential equation, Eq. (2), is recovered up to $O(\Delta t)$.

In implementing the PATHTREE algorithm, good numerical results are obtained in the parameter region defined by the convergence condition

$$\left(\left| g \frac{\partial g}{\partial S_i} \right| dt + g\sqrt{dt} \right) / S_i \ll 1. \quad (14)$$

This insures the proper construction of the tree to order $O(\Delta t)$.

2. Treating binomial oscillations

Binomial trees exhibit by construction a systematic oscillatory behavior as a function of the number of steps in the tree (equivalently, the number of time slices used to build the tree), and the new building algorithm based on the short-time propagator of the path-integral representation of the solution of the Fokker-Planck equation has this same problem. A common practice [20] is to perform averages of runs with consecutive numbers of steps, e.g.,

$$C = \frac{C_{N+1} + C_N}{2}, \quad (15)$$

where C_N signifies the value calculated with N number of steps.

3. Inappropriate trinomial tree

Another type of tree is the trinomial tree discussed above, equivalent to the explicit finite difference method [14,15]. If we were to apply this approach to our new PATHTREE algorithm, we would allow the stochastic variable S to remain unchanged after time step Δt with a certain probability p_m . However, in our construction the trinomial tree approach is not correct, as the deterministic path is dominant in the construction of the probabilities $\{p_u, p_m, p_d\}$, and we would obtain

$$\lim_{\Delta t \rightarrow 0} p_u = p_d = 0,$$

$$\lim_{\Delta t \rightarrow 0} p_m = 1. \quad (16)$$

C. Linear and quadratic aspects of numerical implementation

PATHTREE computes the expected value of a random variable at a later time given the diffusion process and an initial point. The algorithm is similar to a binomial tree computation and it consists of three main steps: computation of a

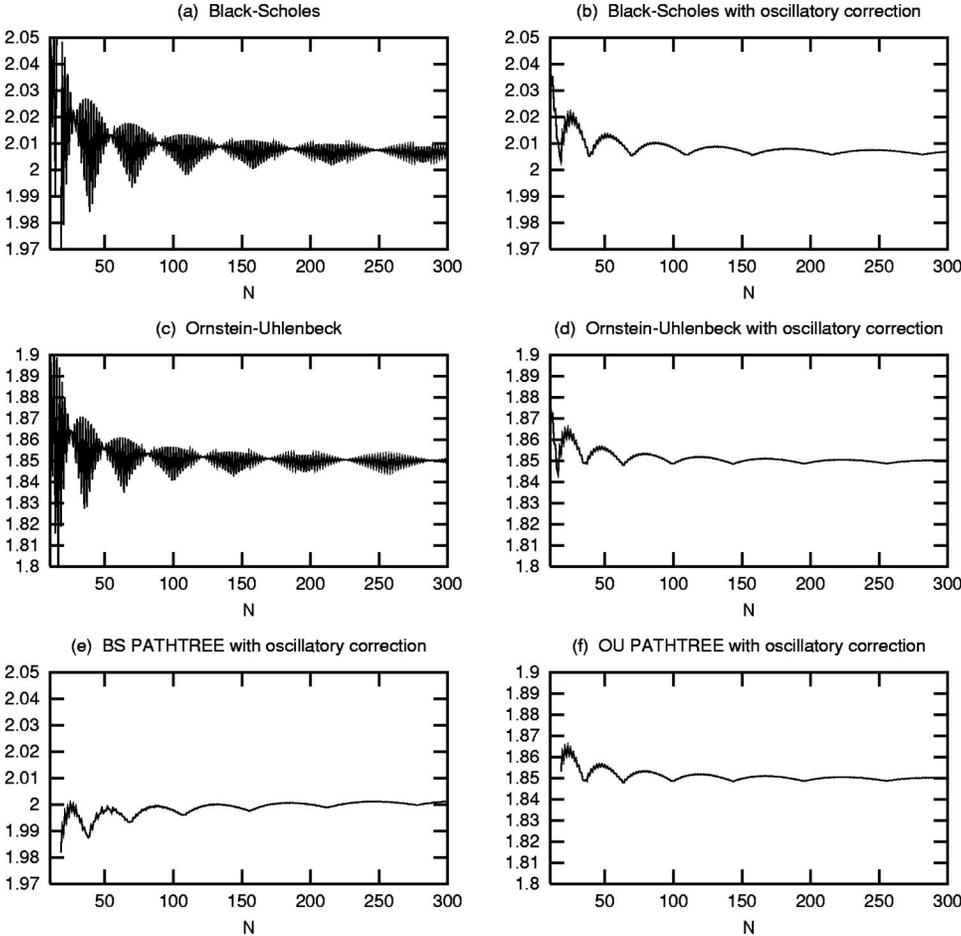

FIG. 1. The oscillatory correction, an average of N and $N+1$ iteration solutions, provides a simple and effective fix to the well-known oscillations inherent to binomial trees. The uncorrected Black-Scholes binomial tree (a) can be compared to the Black-Scholes tree with oscillatory correction (b). In (c), the Ornstein-Uhlenbeck binomial tree can also be robustly corrected as shown in (d). The BS PATHTREE model shown in (e) can be compared to the Black-Scholes case shown in (b). The OU PATHTREE model (f) is equivalent to the Ornstein-Uhlenbeck model in (d). Parameters used in these calculations are: $S=50.0$, $X=55.0$, $T=1.0$, $r=0.0675$, $b=0$, $\sigma=0.20$, and $N=300$.

mesh of points, computation of transition probabilities at those points, and computation of the expected value of the random variable.

The first step is the creation of a one dimensional mesh of points with gaps determined by the second moment of the short term distribution of the process. The mesh is created sequentially, starting from the initial point, by progressively adding to the last point already determined (for the upward part of the mesh) the value of the standard deviation of the short term distribution with the same point as prepoint. In a similar fashion we create the mesh downwards, this time by subtracting the standard deviations. The procedure takes a linear amount of time on the number of time slices being considered and contributes very little to the overall time of the algorithm.

In the second step an array of up and down probabilities is created. These probabilities are the values of the short term transition probability density function obtained by using the current point as prepoint and the two neighboring points as post points. The probabilities are renormalized to sum to unity. This procedure takes a linear amount of time on the number of time slices. Notice that the probabilities only depend on the current point and not on time slice, hence, only two probabilities are computed per element of the array of points.

The third step is the computation of the expected value of the random variable. For example, the option price C is de-

veloped by marching backwards along the tree and applying the risk-neutral evaluation

$$C(S_i, t - \Delta t) = e^{-r\Delta t} [pC(S_{i+1}, t) + qC(S_{i-1}, t)]. \quad (17)$$

We emphasize again that in Itô terms the prepoint value is S_i . This part works as a normal binomial tree algorithm. The algorithm uses the expected values at one time slice to compute the expected values at the previous one. The bulk of the time is spent in this part of the algorithm because the number of iterations is quadratic on the amount of time slices. We managed to optimize this part by reducing each iteration to about ten double precision operations.

In essence, this algorithm is not slower than standard binomial trees and it is very simple to implement.

IV. CALCULATION OF PROBABILITY

A. Direct calculation of probability

We can calculate the probability density function by first recursively computing the probabilities of reaching each node of the tree. This can be performed efficiently, thanks to the Markov property. To compute the density function we need to rescale these probabilities by the distance to the neighboring nodes: the more spread the nodes are, the lower the density. We can estimate the probability density as follows: First we compute the probability of reaching each final

node of the tree. We do this incrementally by first computing the probabilities of reaching nodes in time slice 1, then time slice 2, and so forth. At time slice 0, we know that the middle node has probability 1 of being reached and all the others have probability 0. We compute the probability of reaching a node as a sum of two contributions from the previous time slice. We reach the node with transition pu from the node below at the previous slice, and with transition pd from the node above. Each contribution is the product of the probability at the previous node times the transition to the current node. This formula is just a discretized version of the Chapman-Kolmogorov equation

$$p(x_j, t_i) = p(x_{j-1}, t_{i-1})pu_{j-1} + p(x_{j+1}, t_{i-1})pd_{j+1}. \quad (18)$$

After we have computed the absolute probabilities at the final nodes, we can give a proper estimation of the density, by scaling the probabilities by the average of sizes of the two adjacent intervals, $\text{density}_i = p_i / [(S_{i+2} - S_{i-2})/2]$.

B. Numerical derivatives of expectation of probability

The probability P can be calculated as a numerical derivative with respect to strike X of a European call option, taking the risk-free rate r to be zero, given an underlying S_0 evaluated at time $t=0$, with strike X , and other variables such as volatility σ , cost of carry b , and time to expiration T suppressed here for clarity, $C(S_0, 0; X)$,

$$P[S(T)|S(t_0)] =_{S(T)=X} P[X|S(t_0)] = \frac{\partial^2 C}{\partial X^2}. \quad (19)$$

This calculation of the probability distribution is dependent on the same conditions necessary for any tree algorithm, i.e., that enough nodes are processed to ensure that the resultant evaluations are a good representation of the corresponding Fokker-Planck equation, addressed above, and that the number of iterations in PATHTREE are sufficient for convergence.

1. Alternative first derivative calculation of probability

An alternative method of calculating the probability P as a first-order numerical derivative, instead of as second-order derivative, with respect to X is to define a function C_H using the Heaviside step function $H(S, X) = 1$ if $S \geq X$ and 0 otherwise, instead of the Max function at the time to expiration. This yields

$$P[S(T)|S(t_0)] =_{S(T)=X} P[X|S(t_0)] = -\frac{\partial C_H}{\partial X}. \quad (20)$$

Sometimes this is numerically useful for sharply peaked distributions at the time of expiration, but we have found the second derivative algorithm above to work fine with a sufficient number of epochs.

Our tests verify that the three methods above give the same density. We consider the numerical-derivative calcula-

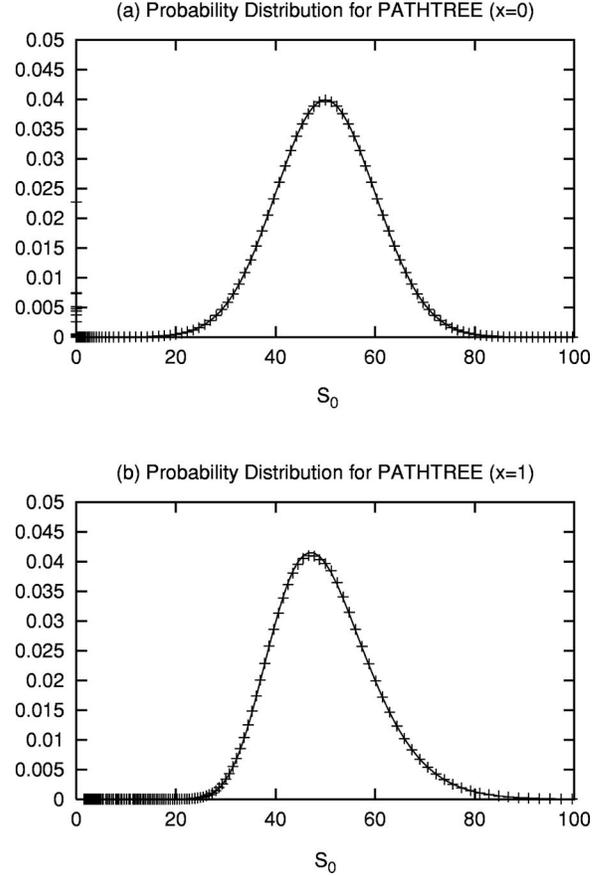

FIG. 2. Probability distributions for the PATHTREE binomial model as described in the text, using second-derivative numerical (“+”s) PATHTREE calculations. In (a), “+” graphs indicate that the OU PATHTREE model agrees well with the exact Ornstein-Uhlenbeck distribution shown in the black line. In (b), “+” graphs indicate that the BS PATHTREE model agrees well with the exact Black-Scholes distribution shown in the black line. Parameters are the same as in Fig. 1.

tions a very necessary baseline to determine the number of epochs required to get reasonable accuracy.

2. Oscillatory corrections

Figure 1 illustrates the importance of including oscillatory corrections in any binomial tree algorithm. When these are included, it is easy to see the good agreement of the BS PATHTREE and OU PATHTREE models.

C. Comparison to exact solutions

Figure 2 gives the calculated probability distribution for the BS and OU models, using the second derivative numerical method, compared to their exact analytic solutions.

V. CONCLUSION

We have developed a path-integral based binomial PATHTREE algorithm that can be used in a variety of stochastic models. This algorithm is simple, fast, and can be applied to

diffusion processes with quite arbitrarily nonlinear drifts and diffusions.

As expected, this PATHTREE algorithm is not as strong as PATHINT [3], as the PATHINT algorithm can include details of an extremely high dimensional tree with complex boundary conditions.

For the PATHINT algorithm, the time and space variables are determined independently. That is the ranges of the space variables are best determined by first determining the reasonable spread of the distribution at the final time epoch. For the PATHTREE algorithm just one parameter, the number of ep-

ochs N , determines the mesh for both time and the space variables. This typically leads to a growth of the tree, proportional to \sqrt{N} , much faster than the spread of the distribution, so that much of the calculation is not relevant.

However, this PATHTREE algorithm is surprisingly robust and accurate. Similar to PATHINT, we expect its accuracy to be best for moderate-noise systems.
